Surgical management of hepatolithiasis: A minireview

Chuan Li, Tianfu Wen*

Department of Liver Surgery, West China Hospital of Sichuan University, Chengdu, China.

Summary

Hepatolithiasis is highly prevalent in Asia but rare in Western countries. However, the incidence of hepatolithiasis may be increasing in Western countries due to the increased rate of immigration from areas where hepatolithiasis is prevalent. There are many nonsurgical treatments for hepatolithiasis, but surgical management remains the best curative treatment for some cases of hepatolithiasis. Surgical treatments can remove biliary stones and relieve stricture of the bile ducts. This review describes the indications for and the outcomes of surgical treatment of hepatolithiasis, including liver resection and liver transplantation.

Keywords: Liver resection, liver transplantation, hepatolithiasis

1. Introduction

The incidence of hepatolithiasis varies. It is highly prevalent in parts of Asia, such as China, Japan, and South Korea, with a reported incidence between 3.1% and 21.2% (1-3). However, hepatolithiasis is rare in Western countries, with an incidence of about 1% (2,4). The mechanism by which hepatolithiasis develops has yet to be fully elucidated. Studies have suggested that cholestasis, cholangitis, an anatomical abnormality of the bile ducts, abnormal bile metabolism, malnutrition, and low socio-economic status are risk factors for hepatolithiasis (5,6). The incidence of hepatolithiasis may decrease in areas where the condition is prevalent because people in those areas have adopted a Western diet. A Japanese nationwide survey reported that the relative prevalence of hepatolithiasis was 4.1% in the years from 1970-1977, 3.0% in the years from 1975-1984, 2.3% in the years from 1985-1988, 2.2% in the years from 1989-1992, and 1.7% in the years from 1993-1995 (6,7). However, the incidence of hepatolithiasis may be increasing in Western countries due to the increasing rate of immigration from areas where hepatolithiasis is prevalent.

2. Surgical treatments

According to Japanese nationwide surveys over a period of 40 years, the primary treatments of hepatolithiasis in the 1970s were cholecystectomy with stone removal and insertion of a T-tube. Surgery was used for primary management of hepatolithiasis until 1998. However, its use later decreased (76.6% in 1998; 52.4% in 2006; 33.3% in 2011, including surgical and non-surgical treatment) (7). In contrast, use of nonsurgical treatments, including endoscopic retrograde cholangiography and percutaneous transhepatic cholangioscopic lithotomy, has markedly increased. However, endoscopic retrograde cholangiography with stone removal results in more residual or recurrent stones than surgery does (7).

3. Indications for hepatectomy

Studies have reported that hepatectomy is indicated for treatment of hepatolithiasis in the following instances: (i) unilobar hepatolithiasis, and particularly that on the left; (ii) atrophy or severe fibrosis of the affected liver segments or lobe; (iii) presence of a liver abscess; (iv) cholangiocarcinoma; and (v) multiple intrahepatic stones causing marked biliary stricture or dilation (8-12).

In China, Dong proposed a system for classification (Table 1) of hepatolithiasis (13). Dong also proposed corresponding treatments for different classes of hepatolithiasis (13). Dong suggested that patients with type 1 or type IIb hepatolithiasis are the best candidates for hepatectomy, whereas patients with type...
Ilc hepatolithiasis should undergo liver transplantation (13). Moreover, a hepaticojejunostomy should also be performed to treat "Eb" and "Ec" hepatolithiasis (13).

### 4. Outcomes of hepatectomy for treatment of hepatolithiasis

Chen et al. (10) reported outcomes for 103 consecutive patients with hepatolithiasis who underwent a hepatectomy between 1989 and 2001. Ninety percent of those patients had immediate stone clearance, and 98% had final stone clearance after subsequent choledochoscopic lithotomy via a T-tube tract or cutaneous stoma (10). Twenty-eight percent of the 103 patients suffered postoperative complications and 2% died (10). Uenishi et al. (14) reported outcomes for 86 patients who underwent a hepatectomy from 1998 to 2012. Seventy-six patients (88%) had immediate stone clearance whereas 82 patients (95%) had final stone clearance (14). Li et al. (15) reported outcomes for 718 patients who underwent a hepatectomy. The immediate stone clearance rate was 93.5% for patients with unilateral hepatolithiasis and 71.1% for patients with bilateral hepatolithiasis. The final clearance rate was 99.3% for patients with unilateral hepatolithiasis and 90.2% for patients with bilateral hepatolithiasis (15). The mortality rate for hepatectomy was 0.4% (15). Yang et al. reported that the immediate stone clearance rate was 81.5% after bilateral hepatectomy and 65.9% after unilateral hepatectomy while the final clearance rate was 85.2% after bilateral hepatectomy and 81.7% after unilateral hepatectomy (16). Liver resection can also be performed on some patients with complex hepatolithiasis. Dong et al. reported outcomes for 12 patients with complex hepatolithiasis who underwent a subtotal hepatectomy (17). After surgery, one patient died from acute purulent cholangitis (17). The remaining 11 patients recovered without recurrent cholangitis (17).

Some techniques may improve the effectiveness with which hepatectomy treats hepatolithiasis. Fang et al. (18) suggested that hepatectomy for bilateral hepatolithiasis based on three-dimensional reconstruction resulted in a higher rate of stone clearance than conventional treatment. Both immediate (96.1% versus 81%) and final clearance rates (100% versus 90.5%) were improved by use of three-dimensional reconstruction (18). Guan et al. also reported similar results (19). Jarufe et al. (20) suggested that anatomical hepatectomy may reduce the incidence of postoperative complications and postoperative recurrence for patients with hepatolithiasis. A study by Jiang et al. (21) suggested that anatomical hepatectomy for treatment of hepatolithiasis was associated with fewer residual stones, fewer infections, and a lower incidence of bile leakage.

### 5. Laparoscopic hepatectomy for treatment of hepatolithiasis

Laparoscopic hepatectomy is a minimally invasive treatment for hepatolithiasis. Laparoscopic treatments may result in satisfactory outcomes for select patients with hepatolithiasis. Lai et al. (22) reported outcomes for 55 consecutive patients with hepatolithiasis who underwent a laparoscopic hepatectomy or bile duct exploration. The immediate stone clearance rate was 90.9% and the final stone clearance rate was 94.5% (22). During the follow-up period, only 3 patients suffered from recurrence (22). Ye et al. (23) reported outcomes for 36 patients who underwent a purely laparoscopic left hemihepatectomy for hepatolithiasis. Residual stones were noted in only 2 patients (23). Stones recurred after surgery in 2 patients (23). Namgoong et al. (24) compared the outcomes of laparoscopic versus open left hemihepatectomy for treatment of hepatolithiasis. Laparoscopic hepatectomy was associated with a longer operating time, briefer hospitalization, a lower postoperative morbidity, and a higher stone clearance rate (24). Ye et al. also noted similar results (25). However, Jin et al. (26) suggested that laparoscopic and open hepatectomy resulted in a similar operating time, duration of postoperative hospitalization, postoperative morbidity, rate of residual stones, and rate of recurrent stones. Recently, a systemic review and meta-analysis by Peng et al. (27) suggested that patients who underwent

a laparoscopic hepatectomy had significantly fewer intraoperative transfusions and overall complications and a significantly briefer duration of hospitalization. However, laparoscopic and open hepatectomy had a similar operating time and resulted in a similar rate of residual and recurrent stones.

6. Factors associated with postoperative recurrence

Many risk factors are associated with the postoperative recurrence of stones. Li et al. (15) found that bilateral stones and limited resection of the liver (i.e., not all segments affected by stones were resected) were two independent risk factors for the postoperative recurrence of stones. A study of surgical and non-surgical treatment of hepatolithiasis suggested that non-surgical treatment, biliary cirrhosis, residual stones, and strictures were risk factors for the recurrence of stones (28). In a study of patients with hepatolithiasis in whom stones were merely removed, Cheung et al. suggested that bilateral stones, strictures, and atrophy were related to the postoperative recurrence of stones (29).

7. Liver transplantation for treatment of hepatolithiasis

Liver transplantation is an effective treatment for terminal hepatolithiasis. According to Dong’s classification, liver transplantation should be undergone by patients with type IIC hepatolithiasis. In 2002, Strong et al. reported 4 liver transplants to treat hepatolithiasis (30). All patients had satisfactory outcomes after liver transplantation. Tang et al. reported a case of a patient with hepatolithiasis and situs inversus who underwent liver transplantation (31). The patient survived as of a 40-month follow-up. Chen et al. reported outcomes for 15 patients with hepatolithiasis who underwent liver transplantation (32). Two of those patients had cholangiocarcinoma. After liver transplantation, the 1-year survival rate was 100% and the 5-year survival rate was 73%. Although studies have suggested that liver transplantation results in satisfactory outcomes for patients with hepatolithiasis, no study has examined this point in a large sample.
