1. Introduction

Most intra-abdominal fibromatosis affect small bowel mesentery (1). However, the omentum, transverse or sigmoid mesocolon, or even ligamentum teres may also be affected (2,3). Omental fibromatosis is a rare benign fibroproliferative process but locally aggressive which may infiltrate the adjacent organs or recur, but do not create distant metastatic lesions (2-4). The term "fibromatosis" was first described by a team of American pathologists in the early 1960s (5). Omental fibromatosis is also termed as intra-abdominal desmoid, is a rare and benign tumour but can be locally aggressive. Majority of cases are asymptomatic, and difficult to diagnose based on clinical presentation and radiological investigation. Final diagnosis is usually made on histopathology and immunohistochemistry studies. Surgical wide excision is currently the treatment of choice.

2. Case Report

A 46-year-old woman, with no medical and surgical history, presented electively for an epigastric hernia cure. Due to chronic diffuse abdominal pain, increased fatigue and weight loss of 2 kg in a few months, it was decided to perform a laparoscopic hernia repair with concomitant exploration of the abdominal cavity. After introduction of the optical trocar in the left flank, exploration revealed greyish-white diffuse nodules of the great omentum, as well as a more localized tumor near the right colonic angle (Figure 1). No mesenteric adenopathy, ascites, or peritoneal implants were identified. The rest of the laparoscopic exploration revealed nothing more. A surgical biopsy was performed. It was decided to stop the procedure in order to obtain anatomopathological results and to provide an accurate diagnosis. The current report presents a case of an omental fibromatosis discovered incidentally in a 46-year-old woman with no particular medical history and few symptoms. A surgical biopsy was performed initially, and microscopic examination revealed myofibroblastic proliferation. After additional immunohistochemical and molecular analyses, omental fibromatosis was diagnosed. Omental fibromatosis, also called intra-abdominal desmoid, is a rare and benign tumour but can be locally aggressive. Majority of cases are asymptomatic, and difficult to diagnose based on clinical presentation and radiological investigation. Final diagnosis is usually made on histopathology and immunohistochemistry studies. Surgical wide excision is currently the treatment of choice.

The retrospective clinical examination was featureless. Tumor markers (CEA, CA 19-9, CA 125) were within the normal range. Thoraco-abdominal CT scan showed only a discrete fat infiltration of the greater omentum, located above the transverse colon, without individualizable nodule (Figure 2).

Macrosopic pathologic examination showed no significant lesions, except for fibrous remodelling (Figure 3a). Microscopic examination revealed adipose tissue with a clearly defined myofibroblastic fusocellular proliferation foci (Figure 3 a, b, and c). After detailed immunohistochemical analysis, fusiform cells expressed smooth muscle actin (SMA), muscle specific actin (MSA) and beta-catenin (Figure 3d), and were negative for S-100 protein and CD-117. The MIB-1 cell proliferation index was very low (< 1%). This myofibroblastic proliferation was morphologically and immunohistochemically consistent with omental fibromatosis. The diagnosis of omental fibromatosis was confirmed by molecular analysis showing that exon 3 of the CTNNB1 gene was present.

After discussion at the local tumor board, it was decided to proceed to a laparoscopic en bloc resection of the greater omentum. Histopathological examination confirmed the lesion as omental fibromatosis.

3. Discussion

Omental fibromatosis is a rare and benign disease occurring in a wide age range of patients, and has no gender or race predilection. Patients have few symptoms and its discovery can sometimes be unexpected during radiological imaging or intraoperatively as in this present case.

Fibromatosis have distinct biological behavior, characterized by initial rapid growth, followed by stability or even regression. Majority of fibromatosis occur sporadically, or in association with Gardner syndrome, familial adenomatosis polyposis coli (FAP) and bilateral ovarian fibromatosis (2,9). Both males and females are affected with equal frequency based on literature review (5). These tumors are not encapsulated and vary widely in size (8). Most tumors measure between 5 and 10 cm in diameter, but they may be as large as 30 cm (10). Predisposing factors are pregnancy, previous abdominal surgery or trauma, and estrogen therapy (1,11-13).

Patients have few symptoms until the tumor reaches a size large enough to cause pain, abdominal fullness, pressure sensation, constipation, and even weight loss (5,8). Most patients with omental fibromatosis are asymptomatic or may present vague abdominal pain, as in this case (2). Some complications that have been reported include small-bowel obstruction and hydronephrosis from ureteric obstruction (14).

The imaging appearance of these tumors is variable and depends on fibroblastic proliferation, fibrosis, collagen content, and vascularity (1). Ultrasonography or computed tomography may be helpful in diagnosis but ultimately, final diagnosis is made by excision and histological examination (2). On ultrasonography,
desmoid tumors have variable echogenicity, appearing as masses of low, medium, or high echogenicity with smooth defined margins (7). Computed tomography images typically demonstrate tumors as solid, well-circumscribed masses of soft tissue density that do not contain calcium, with homogenous enhancement at the periphery and cystic pattern in the central region (8,15).

On macroscopic examination, desmoid tumors are usually circumscribed lesions, but they may have irregular or infiltrating borders, as in this current case. On the surface, they are white and coarsely trabeculated, resembling scar tissue (1). In 10-15% of cases, they are multiple (1). Histologically, desmoid tumors are lesions composed of bland spindled or stellate fibroblastic cells embedded in a collagenous stroma, without evidence of muscular or neural differentiation and with little or no inflammatory component (1). Differential diagnosis includes cysts, sclerosing mesenteritis, mesenteric panniculitis, or tumours originating from smooth muscle, neuronal tissue, adipose and stromal tissue of gastrointestinal tract (2).

Treatment of choice is surgical resection (8). Radiation therapy and/or chemotherapy demonstrated no benefit (16). Surgical approach includes wide local excision of these tumours as they have tendency toward local recurrence in up to 50% (2,8). Some authors recommend a trial of observation with antioestrogens, nonsteroidal anti-inflammatory drugs with limited role of targeted agents such as Imatinib (2,6). There are no clear guidelines for the treatment and follow-up of omental fibromatosis because of its rarity. Therefore, close long-term follow-up should be performed.

In conclusion, omental fibromatosis is usually a benign tumour but can be locally aggressive. Majority of cases are asymptomatic, and difficult to diagnose based on clinical presentation and radiological investigation. Final diagnosis is usually made on histopathology and immunohistochemistry studies. Currently, surgical excision is the only curative method of treatment.
