Summary

The purpose of our study was to identify the mutations in the retinoschisis 1 (\textit{RS1}) gene, which was associated with X-linked retinoschisis (XLRS) in a four-generation Chinese family, and to provide the theoretical basis for gene diagnosis and gene therapy. Genomic DNA was extracted from peripheral leukocytes. All six exons and flanking intronic regions were amplified by polymerase chain reaction (PCR), followed by direct sequencing. Through our genetic analysis, one frameshift 573delG mutation was identified in the patients of this four-generation pedigree; however, this mutation was absent in normal or non-carrier subjects. In conclusion, this 573delG mutation is reported in the Chinese population for the first time. This mutation widens the mutational spectrum of \textit{RS1} in Asians. Identification of mutations in the \textit{RS1} gene and expanded information on clinical manifestations will facilitate early diagnosis, appropriate early therapy, and genetic counseling regarding the prognosis of XLRS.

Keywords: X-linked juvenile retinoschisis, polymerase chain reaction, frameshift mutation, foveal schisis

1. Introduction

X-linked retinoschisis (XLRS) is one of the most common causes of juvenile macular degeneration in males, with an incidence of 1 in 15,000 to 1 in 30,000 (1). The major clinical characteristics of affected males are visual deterioration, foveal-schisis in almost every patient due to the splitting of the retinal cell layers, and a decrease in the b-wave amplitude of the electroretinogram (ERG). Unfortunately, there is no medication to halt the progression of maculopathy, which may induce complete blindness.

XLRS, a recessively inherited disorder, is caused by mutations in the retinoschisis 1 (\textit{RS1}) gene localized at chromosome Xp22.2. The \textit{RS1} gene consists of six exons, and encodes a 224 amino-acid protein named retinoschisin. This protein, has an N-terminal secretory leader peptide and a conservative discoidin domain encoded in exons four to six, and is expressed and secreted from photoreceptors and bipolar cells, where this protein is anchored to the surface of the secreting cells themselves. This protein is presumed to be responsible for normal adhesion and signaling within the retinal cell layers (2,3).

On the basis of previous genetic examinations, a wide spectrum of different mutations in \textit{RS1} have been recorded in the Leiden Open Variation Database, majority of these reported mutations are missense mutations, which primarily exist within exons 4-6 of \textit{RS1} (4). Exons 1-3 tend to have mainly translation truncating nonsense mutations (5). However, the precise correlation between the phenotype and genotype of XLRS still remains unclear.

In our study, we encountered a large XLRS Chinese family where one family member had already lost his sight completely. In the current study, we aimed to identify the molecular variations of XLRS in this Chinese family. We detected the mutations in the \textit{RS1} gene by direct sequencing.
2. Materials and Methods

2.1. Patients and controls

The study protocol, which was carried out in accordance with the tenets of the Declaration of Helsinki, was approved by the ethical committee of Henan provincial people's Hospital. Twenty-four members of the family with XLRS and 40 eligible volunteers as normal controls were recruited for this research. Family history was collected from the proband. Comprehensive ophthalmic examinations included best-corrected visual acuity (BCVA), ERG, optical coherence tomography (OCT), fluorescein angiogram, slit lamp biomicroscopy, and fundus examinations, in order to confirm the diagnosis. Informed consent was obtained from all participants prior to their evaluations in the course of the study.

2.2. Blood collection and DNA extraction

For each subject, venous blood samples (5 mL) were collected into tubes containing EDTA and genomic DNA was extracted using the DNA blood isolation kit. For all probands, exons 1-6 of RS1 PCR was carried out to amplify the exonic regions of RS1, using the primers listed in Table 1. The PCR reaction was performed in a DNA thermocycler (Eppendorf, Hamburg, Germany). The reaction was performed in a total volume of 25 µL containing 2.5 µL 10× buffer (25 mM MgCl2), 0.2 µM each of dNTP, 0.5 µM of each primer, 1 units of Taq DNA polymerase, and 100 ng of genomic DNA. The cycling procedure for the RS1 gene were as follows: 94°C for 5 min, followed by 35 cycles of denaturing at 94°C for 30 sec, annealing for 30 sec at the appropriate temperature for each primer pair, and extension at 72°C for 30 sec. The final extension step was lengthened to 5 min.

2.3. Direct sequencing

All amplified fragments were electrophoresed in a 1.5% agarose gel and purified with a DNA extraction kit. Exons and the flanking intronic regions of RS1 were directly sequenced on an automated sequencer (ABI prism 3130 Genetic Analyzer, Applied Biosystems, CA, USA). The results were compared with the reference sequence of the XLRS sequence variation database.

3. Results

3.1. Clinical findings

The pedigree of interest was a four generation family with twenty-four family members, including four affected males and twenty unaffected individuals based on clinical evaluations (Figure 1). An X-linked pattern of inheritance of disease was shown in the family pedigree. However, a high degree of clinical variability is observed among the patients. The mean age at disease onset was 7.5 years, and the initial clinical presentation was poor visual acuity. The clinical characteristic of the proband was mainly bilateral foveal schisis and no peripheral schisis. The grandfather of the proband (I, Figure 1), therefore, was identified with a more severe clinical manifestation. The patient had typical foveal and peripheral schisis in both eyes, combined with neovascular glaucoma in the right eye, which required surgical intervention. The age of onset, visual acuity, and peripheral and macular involvements for each affected individual are described in Table 2.

Figure 1 depicts the pedigree of the Chinese family with X-linked juvenile retinoschisis. Squares indicate males, and circles indicate females. Dark-shaded boxes represent affected subjects with X-linked juvenile retinoschisis, while non-shaded boxes and circles mark unaffected family members. Circles with a dot denote
Intractable & Rare Diseases Research. 2012; 1(1):30-34.

To the best of our knowledge, over 150 mutations have been recognized (6). To gain insight into the genetic mechanisms and pathogenesis of XLRS, we investigated a large Chinese family with XLRS. Through our thorough clinical examinations and genetic analysis, all four affected males were identified with a single base (G) deletion at the 573 base position in the proband and the other 6 affected males; (C) Heterozygous mutation of the site mentioned above in female carriers.

3.2. Genetic analysis

All exons and the flanking sequence of the RS1 gene were screened for mutation detection in the family. A frameshift mutation at exon 6 due to a G deletion at the 573 base position was identified by direct sequencing of the PCR products in the proband (Figure 2B). All other exons were found to be normal. The proband’s mother (II2, Figure 1), who was clinically normal, showed a heterozygous frameshift mutation (Figure 2C). In addition, this mutation was also detected in the other three affected males (I1, II5, and IV2; Figure 1), and the other five female carriers were found to have a heterozygous condition (II2, III3, III4, IV5, and IV6; Figure 1). All the remaining family members and the matched controls showed a normal sequence (Figure 2A).

4. Discussion

XLRS is an X-linked macular disorder caused by mutations in the RS1 gene. Identification of these mutations is becoming increasingly important in a variety of clinical settings. To the best of our knowledge, over 150 mutations have been recognized (6). To gain insight into the genetic mechanisms and pathogenesis of XLRS, we investigated a large Chinese family with XLRS.
base position (573delG) in exon 6. Moreover, the other three female carriers were found to have a heterozygous condition, while other members of the family and all the healthy controls did not display this mutation. Considering that female carriers are unaffected and the matched controls are not detected to have this mutation, it seems that the absence of a functional RS1 gene was responsible for retinoschisis in affected males in this family and that the disease was transmitted as an X-linked recessive trait (7).

Consequently, this 573delG mutation might shift the open reading frame, resulting in the C-terminal containing a novel set of forty-two amino acids, eleven amino acids longer than the normal protein. It is hypothesized that the activity of this mutant protein may be reduced or completely lost, which would disrupt the signaling pathway and thus lead to destabilization of retinal cell organization and structure (8). To date, this is the first report of the 573delG mutation in the Chinese population, which widens the mutational spectrum of RS1 and is expected to help with diagnosis of this rare genetic disease XLRS in Asians. This identified mutation is present in the hotspot region at amino acid position 192, belonging to the highly conserved discoidin motif of retinoschisin protein, which supports the notion that this domain has functional significance in cell-to-cell adhesion (9). Our results are in agreement with previous findings reported in an Australian population by Hewitt et al. (10).

Although the same frameshift mutation was identified in all four affected males in this family, clinical manifestation of patients within the family exhibited remarkable phenotypic variability, ranging from foveal stellate cystic change to severe bilateral peripheral retinoschisis and highly elevated bullous retinoschisis with vitreous hemorrhage, as well as great variation in age at onset and progression. However, a few studies implied the possibility of a genotype-phenotype relationship. Phenotypes of XLRS were more severe in cases associated with upstream mutations (exons 1-3) in the RS1 gene. Li et al. also reported that the severity of the phenotypes are more likely to relate to the particular mutation types, such as frameshift, splice site, or some missense mutations (11). Comparison of our findings with these previously reported patients of other ethnicities, together with the clinical findings within the reported Chinese family in the current study, presumably reflects that there is no simple phenotype-genotype correlation and that disease severity is not mutation dependent only in XLRS. It is therefore presumed that additional factors, perhaps other genetic influences or unique environmental factors might act as contributors to disease severity (12-14). More investigations on the possibility of a genotype-phenotype correlation and factors causing phenotypic variation are still needed.

In summary, we identified a frameshift deletion 573delG mutation in the Chinese population for the first time. These findings will provide precise diagnosis when a clinical presentation is uncertain early in the course of the disease, as well as confirmation for genetic counseling and prenatal diagnosis for carriers without any symptoms. Elucidation of the mutation spectrum and phenotypic variability in XLRS is still in progress to better understand the pathogenesis of the disease and to facilitate RS1 gene replacement therapy.
