Summary

Alzheimer's disease (AD) is a devastating neurodegenerative disease with progressive loss of memory and cognitive function, pathologically hallmarked by aggregates of the amyloid-beta (Aβ) peptide and hyperphosphorylated tau in the brain. Aggregation of Aβ under the form of amyloid fibrils has long been considered central to the pathogenesis of AD. However, recent evidence has indicated that soluble Aβ oligomers, rather than insoluble fibrils, are the main neurotoxic species in AD. The cellular prion protein (PrP⁰) has newly been identified as a cell surface receptor for Aβ oligomers. PrP⁰ is a cell surface glycoprotein that plays a key role in the propagation of prions, proteinaceous infectious agents that replicate by imposing their abnormal conformation to PrP⁰ molecules. In AD, PrP⁰ acts to transduce the neurotoxic signals arising from Aβ oligomers, leading to synaptic failure and cognitive impairment. Interestingly, accumulating evidence has also shown that aggregated Aβ or tau possesses prion-like activity, a property that would allow them to spread throughout the brain. In this article, we review recent findings regarding the function of PrP⁰ and its role in AD, and discuss potential therapeutic implications of PrP⁰-based approaches in the treatment of AD.

Keywords: PRNP gene, protein misfolding, N1 fragment, Fyn kinase, long-term potentiation (LTP)

1. Introduction

Alzheimer's disease (AD) is one of the most common neurodegenerative diseases, characterized clinically by progressive loss of memory and decline in cognitive function and pathologically by cerebral accumulation of amyloid-beta (Aβ) peptides in extracellular senile plaques and formation of intracellular neurofibrillary tangles constituted by hyperphosphorylated tau protein. The two pathological events are thought to be sequentially associated (1, 2). AD is named after the German psychiatrist and neuropathologist Alois Alzheimer who first described the disease in 1907 (3-5). It is the most common form of dementia, while being a leading cause of death or disability. AD occurs most often in people over 65 years of age, although a less-prevalent early-onset type can occur much earlier. Around 35 million people are estimated to be afflicted with AD worldwide, and the incidence rises exponentially with advancing age, posing a huge challenge for society and health care (6). There are no treatments so far to cure, delay or stop the disease progression. Although the etiology of AD is not fully understood, accumulation of amyloid-beta (Aβ) peptides in the brain is considered the causative component of AD pathogenesis (amyloid hypothesis) (7-10). Aβ peptides of varying length are produced by sequential cleavage of amyloid precursor protein (APP) by β-secretase (mostly β-site APP-cleaving enzyme 1, BACE1) and gamma-secretase (11-14). Compared to Aβ 40 (peptide with 40 amino acid residues), the longer form Aβ 42 (peptide with 42 amino acid residues) has an increased propensity to oligomerize and aggregate to form fibrillar amyloid plaques in the brain, and is widely regarded as the main pathogenic species causing AD. Genetic mutations in APP or preselinin-1 (PS-1) or PS-2 (catalytic subunits of gamma-secretase) lead to overproduction of Aβ 42, and cause early onset AD (15).

Upon failure of all the Aβ-centric approaches that reached Phase III clinical trials, scientists began to question the pathogenic role of amyloid aggregates (senile plaques) that comprise Aβ fibrils, which is the main theme of the amyloid hypothesis (10), and speculate that
the soluble pre-fibrillar Aβ oligomers are most likely the principal toxic forms of Aβ peptide (16-20). Soluble Aβ oligomers are found to be elevated in AD brains, and their levels are strongly correlated with disease onset and severity (21-23). The cellular mechanisms of Aβ oligomer-mediated neurotoxicity are poorly understood. Recent evidence indicate that the Aβ oligomers, also referred to as amyloid-derived diffusible ligands (ADDLs) (22,24,25), may bind to a surface receptor on neurons, thereby initiating signaling transduction pathways that lead to synaptic dysfunction and neuronal death (26-29). One interesting receptor for Aβ oligomers so far identified is the cellular prion protein (PrP\(^C\)) (30), which is a cell membrane glycoprotein ubiquitously expressed but enriched in the brain.

The discovery of PrP\(^C\) as a cell surface receptor for Aβ oligomers has sparked a major interest in research focusing on identification of downstream effectors that mediate the neuronal toxicity and synaptic dysfunction in AD. This subject will be discussed in details later.

2. Cellular prion protein (PrP\(^C\))

Prion diseases are a group of fatal infectious neurodegenerative diseases comprising Creutzfeldt-Jacob disease (CJD), variant Creutzfeldt-Jacob disease (vCJD), Gerstmann-Straussler-Scheinker disease (GSS), fatal familial insomnia (FFI), and Kuru in humans, as well as bovine spongiform encephalopathy (BSE) (otherwise known as mad cow disease) and scrapie (31-32). In prion diseases, the normal PrP\(^C\) is converted into the β-sheet rich, protease-resistant pathogenic form – scrapie prion protein (PrP\(^Sc\)), which is infectious and spreads throughout the brain (33). Stanley Prusiner at the University of California San Francisco (UCSF), USA, first described in 1982 that novel proteinaceous infectious particles (prions) could replicate and propagate without nucleic acids and cause scrapie in animals (31,32). In prion diseases, the normal PrP\(^C\) on its way to the cell surface. The structure of mouse PrP\(^C\) is illustrated in Figure 1 (36). Post-translational modifications of PrP\(^C\) include removal of the N-terminal signal peptide (residues 1-22), N-linked glycosylation at Asn-180 and Asn-196, formation of a disulfide bond between residues 178 and 231, and attachment of a glycosylphosphatidylinositol (GPI) anchor following removal of the C-terminal hydrophobic peptide (residues 231-254) (36-39), rendering a mature PrP\(^C\) with about 210 amino acid residues and a molecular weight of 33-35 kDa. PrP\(^C\) is almost ubiquitously expressed across tissues, with an enrichment in synaptic membranes and astrocytes in the brain.

The precise physiological function of PrP\(^C\) is still unknown. Several pieces of evidence have shown that PrP\(^C\) plays a role in metal ion trafficking (40,41), cell adhesion (42-44), cell survival (36,45), immune regulation (46,47) and signal transduction (26,48,49). PRNP gene knockout mice are developmentally normal and have no signs of neurodegeneration (50,51), indicating that the prion pathology is unlikely to be the result of a loss of PrP\(^C\) function. On the contrary, depletion of neuronal PrP\(^C\) is protective and reverses the disease pathology in scrapie-infected mice (52), presumably due to depletion of the substrate for generation of PrP\(^Sc\) (33). Scrapie infection of transgenic mice expressing PrP\(^C\) lacking the GPI anchor causes efficient prion replication, but no pathology (54). Therefore, normal GPI-anchored PrP\(^C\) is required for the neurotoxicity of PrP\(^Sc\) (55,56).

3. PrP\(^C\): a receptor to mediate Aβ toxicity

It is now widely accepted that the soluble Aβ oligomers are the toxic species that leads to synaptic and cognitive dysfunction as well as neurodegeneration in AD (17,25). This concept is supported by studies showing the strong correlation of the synaptic loss with cortical levels of soluble Aβ species rather than with plaque distribution in AD patients (20,21,24), and the inhibitory effect of soluble Aβ oligomers on long-term potentiation (LTP)
The mechanism of Aβ oligomer toxicity remained largely unknown until the Strittmatter's group at Yale University identified PrP<sup>C</sup> as a receptor capable of mediating the neurotoxic effect of Aβ oligomers (30). To identify candidates for this receptor, they conducted an unbiased expression-cloning screen of a brain cDNA library for binding sites with an oligomeric preparation of synthetic biotinylated Aβ 42 peptides. From more than 225,000 expressed clones, two independent positive clones were isolated and both were found to encode full-length mouse PrP. They found that Aβ 42 oligomers bound to PrP<sup>C</sup> with high affinity and specificity. They then tested the function of this interaction in cultured hippocampal slices, and found that nanomolar concentration of Aβ 42 oligomers potently suppressed CA1 hippocampal LTP and this suppression was not observed in slices generically lacking PrP<sup>C</sup> or in presence of an anti-PrP antibody that blocks the binding of Aβ 42 oligomers to PrP<sup>C</sup>, indicating that the suppression of LTP is specifically mediated by binding of Aβ 42 oligomers to PrP<sup>C</sup> (30). Therefore, they have provided compelling evidence that PrP<sup>C</sup> is a specific binding partner for Aβ 42 oligomers and mediates the inhibitory effect of Aβ 42 on synaptic plasticity.

The Strittmatter's group then sought to test in vivo whether PrP<sup>C</sup> is essential for the ability of brain-derived Aβ to suppress cognitive function. They crossed familial AD transgenes encoding APPswe and PSEN1DeltaE9 into Prnp<sup>-/-</sup> mice, and found that mice lacking PrP<sup>C</sup>, but containing Aβ plaques derived from APPswe/ PSEN1DeltaE9 transgenes, showed no detectable impairment of spatial learning and memory, while the AD transgenic mice with intact PrP<sup>C</sup> exhibited dramatic deficits in spatial learning and memory, indicating that PrP<sup>C</sup> is selectively required for the toxicity of the naturally occurring Aβ in the brain that leads to the cognitive phenotypes in these AD transgenic mice (60), which is in consistency with previous reports that Aβ oligomers isolated from the brain of Alzheimer's patients (20,23,59,61) requires PrP<sup>C</sup> to suppress LTP (62,63).

The Strittmatter's group further found that soluble Aβ assemblies derived from the brains of individuals with Alzheimer's disease interacted with PrP<sup>C</sup> at the postsynaptic density to activate the Src kinase Fyn, which phosphorylates the NR2B subunit of NMDA receptor and causes transient increase of NR2B on the cell surface with consequent excitotoxicity, while rendering destabilization of dendritic spines. Both NR2B phosphorylation and spine destabilization incurred by Aβ oligomers were eliminated in Prnp<sup>-/-</sup> and Fyn<sup>−/−</sup> neurons, indicating a specific association of Aβ-PrP<sup>C</sup>-Fyn-mediated toxic signaling (26,64). This study sheds new light on the molecular mechanism of PrP<sup>C</sup>-mediated Aβ toxicity, while indicating a prion connection of Aβ and Fyn (22,49). Another group further demonstrated that soluble Aβ binds to PrP<sup>C</sup> at neuronal dendritic spines, where it forms a complex with Fyn, and results in the activation of the kinase and subsequent Fyn-dependent tau hyperphosphorylation in a Prnp gene dose-dependent manner (2), making another prion connection that links together the two hallmark pathological events in AD – amyloid accumulation and tau hyperphosphorylation (22,65,66). However, how binding of Aβ oligomers to PrP<sup>C</sup> activates Fyn still remains enigmatic. PrP<sup>C</sup> is an extracellular protein attached to the outer surface of the cell membrane by a GPI anchor, and Fyn is located in the cytoplasm. Current evidence indicates that factors like caveolin-1 or the neural cell adhesion molecule (NCAM) could potentially connect PrP<sup>C</sup> and Fyn from the two opposite sides of the cell membrane (48,67-69).

Two distinct binding sites for Aβ oligomers have been identified on PrP<sup>C</sup> by deletion analysis, antibody binding (30), and biophysical techniques such as site-directed spin labeling and surface plasmon resonance (70). Both sites are rich in positively charged basic residues: one is immediately adjacent to the central region (residues 95-110) and the other is at the extreme N-terminus (residues 23-27) (Refer to Figure 1). It is very likely that the two sites act in concert to render high affinity binding for Aβ oligomers, and deletion of either region results in a major loss of the binding capacity (36,70).

4. PrP<sup>C</sup>: a tale of an "evil angel"

As we know, PrP<sup>C</sup> is converted into an aggregated, β-sheet-rich neurotoxic isoform called PrP<sup>Sc</sup> in prion diseases (33,71). PrP<sup>C</sup> serves not only as the substrate for PrP<sup>Sc</sup> conversion and propagation, but also as a transducer of PrP<sup>Sc</sup>-associated neuronal death (52,56,72). Another noxious function of PrP<sup>C</sup> is to serve as a cell surface receptor for Aβ oligomers to mediate signal transduction leading to neuronal toxicity (26,30,60), which we have already discussed above.

However, this "evil" protein has been found to have numerous beneficial "angel" functions. One notable function is that PrP<sup>C</sup> suppresses glutamate-mediated neuronal excitotoxicity by inhibiting NMDA receptor (36,73). Another function is that PrP<sup>C</sup> physically interacts with the APP cleaving enzyme BACE1 through its N-terminal polybasic domain (residues 23-26) and inhibits its enzyme activity, resulting in a reduction of Aβ production (74-76), which indicates a preventive role against AD. In both cell and animal models, PrP<sup>C</sup> has been shown to lower Aβ production by inhibiting BACE1 (75,76).This function is thought to be modulated by PrPNP polymorphism at codon 129 (M129V), which may be associated with increased risk of AD (77,81). Interestingly, binding of Aβ oligomers to PrP<sup>C</sup> impairs the inhibitory effect of PrP<sup>C</sup> on BACE1 activity (64), which may indicate another mechanism of Aβ oligomer toxicity.

A physiological process that makes PrP<sup>C</sup> a "double-
faced gem” is that PrP<sup>C</sup> undergoes constitutive proteolytic cleavage between residues 111/112, yielding a soluble N-terminal fragment (N1) and a membrane-bound C-terminal fragment (C1), which have a protective role in AD and prion disease, respectively. N1 binds to Aβ oligomers with high affinity, and blocks the neurotoxicity of Aβ oligomers through neutralizing toxic assemblies of Aβ. Therefore, N1 may serve as a potent inhibitor of Aβ oligomer toxicity and represent an entirely new class of therapeutic agents for the treatment of AD (82). N1 is a naturally occurring soluble fragment that is generated by endogenous proteolytic processing of PrP<sup>C</sup> at the α-site (residues 111 and 112) (83), presumably by ADAM (a disintegrin and metalloprotease) proteases (84-87). Blocking ADAM10 synaptic trafficking has been shown to be able to generate a model of sporadic Alzheimer’s disease (88). Agents that could stimulate α-cleavage of PrP<sup>C</sup> should be good drug candidates. On the other hand, the C1 fragment of PrP<sup>C</sup> can inhibit PrP<sup>Sc</sup> formation and accumulation of neurotoxic forms of PrP. The C1 transgenic mice inoculated with PrP<sup>Sc</sup> were found healthy and did not exhibit PrP<sup>Sc</sup> accumulation, indicating that C1 is not a substrate for conversion to PrP<sup>Sc</sup>. Manipulating C1 fragment may thus have therapeutic value for prion diseases (89).

PrP<sup>F</sup> homodimerization has been found to be an important regulator of PrP<sup>C</sup> α-cleavage and stimulate the production of N1 and C1 fragments. The increase of N1 is protective against the toxicity of Aβ oligomers. Thus, manipulation of PrP<sup>F</sup> homodimerization may represent a potential therapeutic avenue against Aβ toxicity in Alzheimer’s disease (90). Interestingly, the APP processing enzyme α-secretase (belongs to ADAM family of zinc metalloproteases), which precludes Aβ production by cleaving APP within the Aβ domain (91), also cleaves PrP<sup>F</sup> at the α-site (residues 111 and 112), releasing N1 from the membrane. Therefore, enhancing the activity of α-secretase may represent a novel therapeutic strategy by reducing the toxic Aβ production and increasing the protective N1 production (92).

5. AD: a story of two prions

The misfolding and aggregation of Aβ and tau proteins were traditionally thought to contribute in parallel to pathogenesis of AD. Accumulating evidence indicated that misfolded, toxic oligomers of Aβ and tau spread through the brain in a way much like misfolded PrP (93-95). The misfolded forms of Aβ or tau have a seeding effect, and can induce normal Aβ or tau in the cells to misfold, spread and become toxic (96-102). Therefore, AD can be regarded as a disease that harbors two proteins with prion-like behavior: Aβ and tau (103,104). The prion-like propagation of additional proteins whose misfolding into β-sheet-rich structures underlies other well-known neurodegenerative diseases has also been indicated (105-107). Thus, a prion-based mechanism is proposed to unite a wide array of neurodegenerative diseases, all of which may stem from misfolded proteins self-propagating through the brain (103,108). Local injection of misfolded Aβ in the brains of AD transgenic mice has been found to trigger the misfolding and spreading of otherwise normal Aβ throughout the brain, indicating the prion-like activity of Aβ (108-114). Injection of AD brain extracts into the hippocampus of mice expressing human wild-type APP induces Aβ deposition, which progressively increases over time after inoculation and spreads to brain areas far from the injection site, where other Aβ-related pathology is also observed (114). It is believed that certain Aβ conformations tend to self-propagate, and targeting those specific Aβ assemblies may interrupt the spread of Aβ deposition, hence exerting therapeutic effect on AD (109).

Intracerebral injection of aggregation-prone mutant tau in mice has also been demonstrated to induce wild-type tau to form neurofibrillary tangles and spread throughout the brain (99). Accumulating evidence indicates that Aβ works upstream of tau in AD pathogenesis (65,115-121). Aβ can bind to tau and induce formation of tau oligomers, which can then self-propagate without additional Aβ, indicating a cross talk between the two prions (104).

6. PrP<sup>F</sup>: a novel therapeutic target for AD

PrP<sup>F</sup> has been identified as a major player in mediating the toxicity of Aβ oligomers that leads to synaptic loss and cognitive impairment in AD. Therefore, targeting PrP<sup>F</sup>, its interaction with Aβ oligomers, or downstream mediators can be considered the new line of choice for therapeutic development for treatment of Alzheimer’s disease.

Genetic ablation of PrP<sup>F</sup> in mice rescues the neurotoxic phenotypes of Aβ oligomers (30,60). It might be reasonable to speculate that using shRNA or siRNA to knock down the expression of PrP<sup>F</sup> may represent a therapeutic approach for AD, though little has been done in this regard. Nevertheless, knocking down PrP<sup>F</sup> will also affect other functions of PrP<sup>F</sup>, causing various complications. For example, PrP<sup>F</sup> reduces Aβ production by inhibiting BACE1 activity, and has a protective role in AD (74,75). This can be jeopardized by PrP<sup>F</sup> knockdown.

Attempts have been made to seek antibodies that could efficiently bind to PrP<sup>F</sup> and block the binding site(s) of Aβ oligomers, which may have therapeutic effect on AD by preventing the Aβ oligomer/PrP<sup>F</sup>-initiated noxious signaling. Michael Rowan group at University College Dublin in the U.K. found that antibodies against the epitopes at the PrP principal Aβ-binding site and helix-1 were able to block Aβ binding and block the Aβ-mediated disruption of synaptic functions.
plasticity (63). Chung et al. from New York University School of Medicine intraperitoneally injected the monoclonal anti-PrP antibody, 6D11, in APP/PS1 transgenic mice, and found that the treatment with 6D11 antibody completely rescue the cognitive and behavioral deficits of the transgenic animals (122). The 6D11 antibody is directed against the epitope (residues 93-109), which is the region suggested to be involved in Aβ oligomer binding.

Screening for small molecules that could efficiently target either the Aβ oligomer/PrP\textsuperscript{C} interaction or the downstream mediators may represent a promising avenue for therapeutic development.

The Fyn kinase has been found to be activated upon binding of Aβ oligomers with PrP\textsuperscript{C}, which then initiate downstream signaling to mediate Aβ toxicity, for example, activation of Fyn kinase lead to hyperphosphorylation of tau (2,66). Targeting Fyn kinase or other Aβ/PrP\textsuperscript{C} downstream mediators, for example by genetic engineering, RNAi, or small molecule modulators, may also be of therapeutic value.

Synthetic N1 fragment, equivalent of that released by α-cleavage of endogenous PrP\textsuperscript{C}, has been found to bind Aβ oligomers with high affinity, sequester Aβ oligomers in the extracellular space, and hence block the Aβ oligomer-mediated synaptic toxicity (82). Therefore, exogenous administration of N1 or enhancement of endogenous α-cleavage of PrP\textsuperscript{C} represents a brand-new class of therapeutic approaches for AD. Among others, seeking modulators that prevent Aβ oligomerization or inhibit the prion-like activity of Aβ or tau may represent another category of therapeutic development strategies for the treatment of AD.

The ‘PrP\textsuperscript{C} axis’ of therapeutic development strategies for AD is illustrated in Figure 2.

7. Discrepancies

The Strittmatter group’s discovery of PrP\textsuperscript{C} as an Aβ oligomer receptor to mediate synaptotoxicity has created an exciting hot spot, which has greatly stimulated research in the field. However, studies from different groups around the world showed discrepancies and some groups came to a completely opposite conclusion to the Strittmatter group’s, which made scientists begin to question the role of PrP\textsuperscript{C} in mediating the toxic effects of Aβ oligomeric assemblies.

The work published in Nature a year later from Roberto Malinow’s group at the University of California at San Diego in the USA reported that PrP\textsuperscript{C} is not required for Aβ-induced synaptic toxicity, having raised a conflicting concern that Aβ-mediated synaptic defects do not require PrP\textsuperscript{C}. The Aβ-induced depression of synaptic transmission was observed in both wild-type and Prnp\textsuperscript{−/−} mouse slices (123).

Gianluigi Forloni and his team at the Mario Negri Institute for Pharmacological Research in Italy injected Aβ 42 oligomers into the lateral ventricle of C56BL/6 mice and found that PrP-expressing and PrP knock-out mice were equally susceptible to cognitive impairment.

---

**Figure 2. Therapeutic development strategies for AD (The ‘PrP\textsuperscript{C} axis’).** The green color portion of PrP\textsuperscript{C} indicates the protective function of PrP\textsuperscript{C} (left-hand side), and the red color portion of PrP\textsuperscript{C} indicates PrP\textsuperscript{C} as the receptor of Aβ oligomers (right-hand side) to mediate the Aβ toxicity. The left-hand side of the figure indicates therapeutic strategies by enhancing the normal function of PrP\textsuperscript{C} (enhancing the inhibitory effect on BACE1, which reduces Aβ production, and enhancing the α-cleavage, which increases production of the protective N1 fragment of PrP\textsuperscript{C}). The right-hand side of the figure indicates therapeutic strategies by targeting the Aβ oligomer/PrP\textsuperscript{C}-mediated toxic signaling pathway, which encompass measures to inhibit Aβ oligomerization, Aβ prion-like activity, interaction of Aβ oligomers with PrP\textsuperscript{C}, Aβ oligomer/PrP\textsuperscript{C}-mediated disinhibition of BACE1, intermediate mediators (such as caveolin-1 and NCAM), Fyn kinase, and prion-like activity of hyperphosphorylated Tau. (Abbreviations: Aβo: Aβ oligomers; N1: N1 fragment of PrP\textsuperscript{C}; p-Tau: hyperphosphorylated Tau.)

www.irdrjournal.com
suggesting that PrP<sup>C</sup> is not required for Aβ 42 oligomer-mediated cognitive impairment, although they in the meantime confirmed that Aβ 42 oligomers do interact with PrP<sup>C</sup> with nanomolar affinity (124).

Andriano Aguzzi and his group at the University Hospital Zurich in Switzerland have also reported findings that challenge the role of PrP<sup>C</sup> as an Aβ toxicity mediator. They found that deletion or overexpression of PrP<sup>C</sup> had no effect on the impairment of hippocampal synaptic plasticity, while having also confirmed the efficient binding of Aβ 42 oligomers to PrP<sup>C</sup> (125), once again showing contradictory results to those of Strittmatter and his team (30,60).

However, those conflicting reports do not necessarily negate the findings of Strittmatter and his team. They might arise from differences in animal models, experimental settings, and preparations of Aβ oligomers (method of preparation, material source, and size and conformation of Aβ oligomeric assemblies may all matter) (126).

A recent study from Michael Rowan group at University College Dublin in the U.K., which we have mentioned previously, clearly shows that PrP is required for the plasticity-impairing effects of toxic Aβ species from human AD brain and that standardized ADDL preparations disrupt hippocampal synaptic plasticity in a PrP-dependent manner (63). They further found that antibodies that block Aβ binding to PrP<sup>C</sup> block the toxic effect on synaptic plasticity.

Sylvain Lesne group at the University of Minnesota in the USA has recently demonstrated that soluble Aβ binds to PrP<sup>C</sup> at neuronal dendritic spines, where PrP<sup>C</sup> is enriched, and causes hyperphosphorylation of tau by activation of the Fyn kinase. The PrP<sup>C</sup> antibody 6D11 prevents Aβ oligomers from binding to PrP<sup>C</sup>, and abolishes subsequent Fyn activation and Fyn-dependent tau hyperphosphorylation.

There are also other studies that have indicated a role of PrP<sup>C</sup> in mediating the toxicity of Aβ oligomers, supporting the findings of the Strittmatter group (64,127). Therefore, the argument is far from conclusive.

8. Concluding remarks and perspectives

Although there are conflicting reports regarding the function of PrP<sup>C</sup> as a cell surface receptor to mediate the deleterious effects of Aβ oligomers in AD, there are no ambiguities for two end points: high affinity binding of Aβ oligomers to PrP<sup>C</sup> (30,70,124,125), and high synaptic toxicity of Aβ oligomers (23,59-61). The challenge remaining for scientists is to ‘make the two ends meet’.

Strittmatter group’s finding that PrP<sup>C</sup> acts as the receptor for mediating Aβ oligomer neurotoxicity (30) has at least opened a new direction towards understanding the molecular mechanism that connect Aβ oligomers and their toxic effects. The research discoveries of his team have apparently been supported by multiple studies from other groups, though there have been conflicting results reported. Sophisticated studies using advanced animal models and optimized experimental conditions are needed to elucidate the precise role of PrP<sup>C</sup> in mediating Aβ oligomer neurotoxicity, or to identify other potential cell surface receptors and signaling networks that make the two ends – toxin and toxicity – meet.

If the role of PrP<sup>C</sup> in Aβ oligomer-mediated pathogenic process turns out to be substantial, it would be of interest to seek potential co-receptors or to examine whether other Aβ-mediated signaling pathways are also PrP<sup>C</sup>-dependent, making a complete prion connection network of AD.

To conclude, endeavors to gain precise understanding of the Aβ oligomer-mediated neurotoxic signaling pathways will greatly facilitate the development of novel therapies that would be able to target specific Aβ oligomeric assemblies and their downstream associates, and offer new hope to AD patients and families. Identification of the biophysical features of naturally occurring toxic Aβ species in human AD brain would be of critical reference to clinically relevant translational research.
